Probabilistic Pursuit–Evasion Games: Theory, Implementation, and Experimental Evaluation

René Vidal, *Student Member, IEEE*, Omid Shakernia, *Student Member, IEEE*, H. Jin Kim, *Associate Member, IEEE*, David Hyunchul Shim, *Member, IEEE*, and Shankar Sastry, *Fellow, IEEE*

Abstract—We consider the problem of having a team of unmanned aerial vehicles (UAVs) and unmanned ground vehicles (UGVs) pursue a second team of evaders while concurrently building a map in an unknown environment. We cast the problem in a probabilistic game theoretical framework, and consider two computationally feasible greedy pursuit policies: *local-max* and *global-max*. To implement this scenario on real UAVs and UGVs, we propose a distributed hierarchical hybrid system architecture which emphasizes the autonomy of each agent, yet allows for coordinated team efforts. We describe the implementation of the architecture on a fleet of UAVs and UGVs, detailing components such as high-level pursuit policy computation, map building and interagent communication, and low-level navigation, sensing, and control. We present both simulation and experimental results of real pursuit–evasion games involving our fleet of UAVs and UGVs, and evaluate the pursuit policies relating expected capture times to the speed and intelligence of the evaders and the sensing capabilities of the pursuers.

Index Terms—Autonomous vehicles, multiagent coordination and control, multirobot systems, pursuit–evasion games.

I. INTRODUCTION

THE BErkeley AeRobot (BEAR) project is a research effort at the University of California at Berkeley that encompasses the disciplines of hybrid systems theory, navigation, control, computer vision, communications, and multiagent coordination. The goal of our research is to integrate multiple autonomous agents with heterogenous capabilities into a coordinated and intelligent system that is modular, scalable, fault tolerant, adaptive to changes in task and environment, and able to efficiently perform complex missions. This paper highlights the theory, implementation, and evaluation of probabilistic pursuit–evasion games on the BEAR test bed of unmanned aerial vehicles (UAVs) and unmanned ground vehicles (UGVs) shown in Fig. 1.

In this scenario, a team of UAV and UGV *pursuers* attempts to capture *evaders* within a bounded but unknown environment.

Fig. 1. Berkeley AeRobot test bed for pursuit–evasion games.

We cast the problem in a probabilistic game theoretical framework that combines pursuit–evasion games and map building in a *single* problem, which avoids the conservativeness inherent to classical worst-case approaches. We consider two computationally feasible pursuit policies: *local-max* and *global-max*. We prove that for the global-max policy, there exists an upper bound on the expected capture time which depends on the size of the arena, and the speed and sensing capabilities of the pursuers.

In order to implement this pursuit–evasion game scenario on a fleet of UAVs and UGVs, we propose a distributed hierarchical hybrid system architecture that segments the control task into different layers of abstraction: high-level pursuit policy computation, map building and interagent communication, and low-level tactical planning, navigation, regulation, and sensing. Our architecture is modular and scalable, allowing one to "divide and conquer" a complex large-scale system by developing and integrating simpler components. Unlike the traditional *sense–model–plan–act* decomposition, our architecture takes into consideration the dynamics of each agent so that our system can achieve real-time performance.

We evaluate the proposed probabilistic framework and hierarchical architecture through simulation and experimental results on our fleet of UAVs and UGVs. Using the expected capture time as the performance criterion, we compare the local-max and global-max pursuit policies on numerous situations, varying the speed and intelligence of the evaders and the sensing capabilities of the pursuers. Our experimental results show that the global-max policy outperforms the local-max policy in a realistic situation, in which the dynamics of each agent are included and computer vision is used to detect the evaders. Furthermore, our experiments show that the global-max policy is robust to

changes in the conditions of the game. Even though it is designed for a randomly moving evader, the policy is also successful in catching an intelligent evader.

A. Previous Research in Pursuit–Evasion Games

The classical approach to pursuit–evasion games is to first build a map of the terrain and then play the game in a known environment. For the map-building stage, several techniques have been proposed, see, e.g., [1] and references therein. Most of them are based on Bayesian estimation and are implemented using the Extended Kalman Filter. The main problem with these map-building techniques is that they are time consuming and computationally expensive, even in the case of simple two-dimensional (2-D) rectilinear environments [2]. On the other hand, most of the literature in pursuit–evasion games, see e.g., [3]–[6], assumes worst-case motion for the evaders and an accurate map of the environment. In practice, this results in overly conservative pursuit policies applied to inaccurate maps built from noisy measurements.

In [7], the pursuit–evasion game and map-building problems are combined in a single probabilistic framework. The basic scenario considers multiple pursuers trying to capture a single randomly moving evader. In [8], we extended the scenario to consider multiple evaders, and proposed a simple vision-based algorithm for evader detection. We also included supervisory agents, such as a helicopter, that can detect evaders but not capture them. In parallel with our theoretical work on pursuit–evasion games, we have been developing a test bed for multiagent coordination and control. In [9], we presented a real-time control system for regulation and navigation of a UAV. In [8], we presented an architecture for pursuit–evasion games, and described the implementations of the navigation, communication, and sensing layers. In [10], we presented the implementation of the high-level mission coordination, including the components for pursuit policy computation and map building.

Recent work on pursuit–evasion games considers evaders that actively avoid the pursuers, as described in [11], where a dynamic programming solution to a Stackelberg equilibrium of a partial-information Markov process is proposed. There has also been work on vision-based pursuit–evasion games, where the pursuers use optical flow to determine the number of moving evaders as well as their position and orientation [12]. Implementation and evaluation of these two techniques is forthcoming.

B. Previous Research in Multirobot Systems

The multiagent pursuit–evasion game scenario considered in this paper fits within the general framework of multirobot systems. There exists a large body of literature in multirobot systems addressing problems such as machine-learning techniques for multiagent systems [13], hybrid algorithms for multiagent control [14], multirobot localization [15], distributed sensor fusion [16], and formation control [17].

As for application of multirobot systems in robot soccer, we refer the reader to [18] and [19] for centralized coordination and control of multiple robots, and to [20] and [21] for completely distributed systems.

II. PURSUIT–EVASION SCENARIO

This section describes the theoretical foundations for probabilistic pursuit–evasion games, including map building, pursuit policies, and evasion policies. We also describe a vision-based algorithm for obstacle and evader detection.

Notation. We denote by $(\Omega, \mathcal{F}, \mathrm{P})$ the relevant *probability space* with Ω the set of all possible events related to the pursuit–evasion game, $\mathcal{F}$ a family of subsets of Ω forming a σ algebra, and $\mathrm{P} \colon \mathcal{F} \to [0, 1]$ a probability measure on $\mathcal{F}$. Given two sets of events $A, B \in \mathcal{F}$ with $\mathrm{P}(B) \neq 0$, we write $\mathrm{P}(A|B)$ for the *conditional probability of A given B*. Boldface symbols are used to denote random variables.

A. Probabilistic Framework

Consider a finite 2–D environment $\mathcal{X}$ with n_c square cells containing an unknown number of fixed obstacles, and let $\mathbf{x}_p \subset \mathcal{X}$ ($\mathbf{x}_e \subset \mathcal{X}$) be the set of cells occupied by the n_p pursuers (n_e evaders). Pursuers and evaders are allowed to move to cells in $\mathcal{X}$ in which there is no other pursuer, evader, or obstacle.

Each pursuer (evader) collects information about $\mathcal{X}$ at discrete time instants $t \in \mathcal{T} \overset{\Delta}{=} \{1, 2, \ldots\}$. Each measurement $\mathbf{y}(t)$ is a triple $\{\mathbf{v}(t), \mathbf{e}(t), \mathbf{o}(t)\}$ taking values in a measurement space $\mathcal{Y}$, where $\mathbf{v}(t)$ denotes the measured positions of the pursuers, and $\mathbf{e}(t)$ ($\mathbf{o}(t)$) is a set of cells where evaders (obstacles) are detected. We let $\mathcal{Y}^*$ be the set of all finite sequences of elements in $\mathcal{Y}$, and $\mathbf{Y}_t \in \mathcal{Y}^*$ be the sequence of measurements $\{\mathbf{y}(1), \ldots, \mathbf{y}(t)\}$ taken up to time t. In practice, measurements are taken within a certain subset of $\mathcal{X}$: *the visibility region*. We denote the visibility region of pursuer k (evader i) at time t as $V_{p_k}(t)$ ($V_{e_i}(t)$).

Sensor information is assumed to be imperfect. We use a simple sensor model based on the probability of false positives $p \in [0, 1]$ and false negatives $q \in [0, 1]$ of a pursuer detecting an evader or an obstacle. However, we assume that pursuers have perfect knowledge of their own locations, that is $\mathbf{v}(t) = \mathbf{x}_p(t)$.[1]

Capture of an evader is defined as follows: Let $x_{p_k}(t) \in \mathbf{v}(t)$ and $x_{e_i}(t) \in \mathbf{e}(t)$ be the estimated positions of ground pursuer k and evader i at time t, respectively. We say that evader i is captured by ground pursuer k at time t if $x_{e_i}(t) \in V_{p_k}(t)$ and $d(x_{p_k}(t), x_{e_i}(t)) \leq d_m$, where $d(\cdot, \cdot)$ is a metric in $\mathcal{X}$ and d_m is a prespecified *capture distance*. Captured evaders are removed from the game. The *capture time* of all evaders is defined as $\mathbf{T}^* = \max_{i=1 \ldots n_e} \mathbf{T}_i^*$, where $\mathbf{T}_i^*$ is the time instant at which evader i is captured. We assume that aerial pursuers can detect and share information about the positions of evaders, but not capture them.

B. Map Building

We assume that pursuers are able to identify each evader separately, and that each evader moves independently of the other evaders. Therefore, without loss of generality, we will assume $n_e = 1$ and omit the subscript identifying each evader. Let $p_e(x, \tau | Y_t)$ be the posterior probability of the evader being

---

[1]This assumption is unrealistic in general, although valid when a global positioning system (GPS) is used for pursuer localization and vision is used for evader detection.

in cell x at time τ, given the measurement history $\mathbf{Y}_t = Y_t$. Similarly, let $p_o(x|Y_t)$ be the conditional probability of having an obstacle in cell x given Y_t. At each t, pursuers have estimates of the evader and obstacle *maps* $p_e(x, t|Y_{t-1})$ and $p_o(x|Y_{t-1})$, obtain a new measurement $\mathbf{y}(t)$, and recursively estimate $p_o(x|Y_t)$ and $p_e(x, t + 1|Y_t)$ in three steps. First, pursuers compute $p_e(x, t|Y_t)$ as

$$
\begin{cases}
0 \text{ if } x \in \mathbf{o}(t) \cup \mathbf{v}(t) \setminus \mathbf{e}(t), & \text{or the evader is captured} \\
\alpha p_e(x, t|Y_{t-1}) P(e|x, v, Y_{t-1}), & \text{otherwise}
\end{cases}
\tag{1}
$$

where α is a normalizing constant independent of x, and $P(e|x, v, Y_{t-1}) = P(\mathbf{e}(t) = e|\mathbf{x}_e(t) = x, \mathbf{v}(t) = v, \mathbf{Y}_{t-1} = Y_{t-1})$

$$
= \begin{cases}
0, & x \in \mathbf{v}(t) \\
p^{k_1}(1-p)^{k_2} q^{k_3} (1-q)^{k_4}, & \text{otherwise.}
\end{cases}
\tag{2}
$$

Here, for each x, k_1 is the number of false positives, k_2 is the number of true negatives, k_3 is the number of false negatives, and k_4 is the number of true positives. Recall that p and q are the probability of the sensor reporting false positives and false negatives, respectively.

Second, pursuers compute the obstacle map $p_o(x|Y_t)$ as

$$
\begin{cases}
\dfrac{(1-q)p_o(x|Y_{t-1})}{(1-q)p_o(x|Y_{t-1})+p(1-p_o(x|Y_{t-1}))}, & x \in V_p(t) \cap \mathbf{o}(t) \\[2ex]
\dfrac{qp_o(x|Y_{t-1})}{qp_o(x|Y_{t-1})+(1-p)(1-p_o(x|Y_{t-1}))}, & x \in V_p(t) \setminus \mathbf{o}(t) \\[2ex]
1, & x \in \mathbf{v}(t) \cap \mathbf{o}(t) \\[1ex]
0, & x \in \mathbf{v}(t) \setminus \mathbf{o}(t) \\[1ex]
p_o(x|Y_{t-1}), & \text{otherwise}
\end{cases}
\tag{3}
$$

where $V_p(t) = \bigcup_{k=1}^{n_p} V_{p_k}(t)$.

Finally, in order to compute $p_e(x, t+1|Y_t)$, pursuers assume a Markov model for the motion of the evader which is determined by the probability $\rho \in [0, 1/8]$ that the evader moves to an unoccupied cell in $\mathcal{A}(x)$, where $\mathcal{A}(x)$ is the set of (up to eight) cells adjacent to x. The evader map $p_e(x, t+1|Y_t)$ is updated as

$$
(1 - |\mathcal{A}(x)|\rho)p_e(x, t|Y_t) + \rho(1 - p_o(x|Y_t)) \sum_{\overline{x} \in \mathcal{A}(x)} p_e(\overline{x}, t|Y_t).
\tag{4}
$$

C. Pursuit Policies

Given the measurement history $\mathbf{Y}_t$, the pursuers need to decide where to move at the next time instant. Let $\mathbf{u}(t) \triangleq [\mathbf{u}_1(t), \ldots, \mathbf{u}_{n_p}(t)]$ be the desired position of the pursuers at time t. Since two pursuers must not occupy the same cell, $\mathbf{u}(t)$ is an element of the control action space $\mathcal{U} \triangleq \{\{v_1, \ldots, v_{n_p}\}: v_i \in \mathcal{X}, v_i \neq v_j \text{ for } i \neq j\}$. We define a *pursuit policy* as the random function $\mathbf{g}: \mathcal{Y}^* \to \mathcal{U}$

$$
\mathbf{g}(\mathbf{Y}_t) \triangleq \mathbf{u}(t+1) = [\mathbf{u}_1(t+1), \ldots, \mathbf{u}_{n_p}(t+1)].
\tag{5}
$$

We measure the performance of a specific pursuit policy $\overline{g}$ by the expected capture time $E_{\overline{g}}[\mathbf{T}^*] \triangleq E[\mathbf{T}^*|\mathbf{g} = \overline{g}]$. Since the dependence of $E_{\overline{g}}[\mathbf{T}^*]$ on the pursuit policy $\overline{g}$ is, in general, very complex [7], instead of finding the optimal policy that minimizes $E_{\overline{g}}[\mathbf{T}^*]$, we look for efficiently computable suboptimal

policies with good performance. To this end, we first introduce the notion of a persistent pursuit policy [7] and show that it guarantees a certain degree of success for the pursuers. We then present two computationally efficient greedy policies and show that one of them satisfies the persistence property, given certain assumptions on the distribution of the obstacles and the sensing models.

1) Persistent on the Average Pursuit Policies: A specific pursuit policy $\overline{g}: \mathcal{Y}^* \to \mathcal{U}$ is said to be *persistent on the average* if there is an integer T and some $\epsilon > 0$, such that for each $t \in \mathcal{T}$, the conditional probability of capturing evader i on the set of T consecutive time instants starting at t is greater than or equal to ϵ, i.e.

$$
P(\mathbf{T_i}^* \in \{t, t+1, \ldots, t+T-1\}|\mathbf{g} = \overline{g}, \mathbf{T_i}^* \geq t) \geq \epsilon.
\tag{6}
$$

We call T the *period of persistence*. Persistent on the average pursuit policies satisfy the following [7]:

Lemma 1: If $\overline{g}: \mathcal{Y}^* \to \mathcal{U}$ is a persistent on the average pursuit policy with period T, then $P(\mathbf{T_i}^* < \infty|\mathbf{g} = \overline{g}) = 1$, and $E_{\overline{g}}[\mathbf{T_i}^*] \leq T\epsilon^{-1}$, with ϵ as in (6).

Lemma 1 shows that for a pursuit policy which is persistent on the average, the probability of capturing evader i in finite time is equal to one. Moreover, *Lemma 1* gives a simple upper bound on the expected capture time for evader i. The following lemma (proved in [22]) gives a sufficient condition for a policy to be persistent on the average.

Lemma 2: Let $\mathcal{Y}_t^{\neg \text{fnd}}$, be the set of all sequences of measurements of length t, associated with evader i not being found up to time t. A sufficient condition for a pursuit policy $\overline{g}$ to be persistent on the average with period T is the existence of some $\delta > 0$, such that for each $t \in \mathcal{T}$ and each $Y \in \mathcal{Y}_{t+T-2}^{\neg \text{fnd}}$, there is some $\tau \in \{t - 1, t, \ldots, t + T - 2\}$ for which $P(\mathbf{T_i}^* = \tau + 1|\mathbf{Y}_\tau = Y_\tau, \mathbf{g} = \overline{g}) \geq \delta$. In this case, (6) holds with

$$
\epsilon \triangleq \begin{cases}
\dfrac{1}{T}\left(1 - \dfrac{1}{T}\right)^{T-1}, & \delta \geq \dfrac{1}{T} \\[2ex]
\delta(1 - \delta)^{T-1}, & \delta < \dfrac{1}{T}.
\end{cases}
\tag{7}
$$

2) Admissible Policies, Obstacle Density, and Sensor Models: In order to apply *Lemmas 1* and *2* to a specific pursuit policy, we will need some extra assumptions on the dynamics of the pursuers, the distribution of the obstacles, and the sensor models used for evader detection.

First, we restrict our attention to pursuit policies that respect the dynamics of each vehicle. Let $\mathcal{U}_{p_k}(x_{p_k}) \subset \mathcal{X}$ be the set of cells that pursuer k can reach from cell x_{p_k} in one time step, provided that those cells are empty, and let $\mathcal{U}(x_p) \triangleq \prod_{k=1}^{n_p} \mathcal{U}_{p_k}(x_{p_k})$.[2] We say that a pursuit policy $\overline{g}$ is *admissible* if for every sequence of measurements $Y \in \mathcal{Y}^*$, we have $\overline{g}(Y) \in \mathcal{U}(x_p)$, where $x_p = (x_{p_1}, \ldots, x_{p_{n_p}})$ are the pursuers' positions specified by the last measurement in Y.

Next, we assume that the density of obstacles in the environment is small enough so that any cell in $\mathcal{X}$ can be reached in a finite amount of time. More formally

---

[2]The one-step reachable set $\mathcal{U}_{p_k}(x_{p_k})$ can be computed offline as a parametric function of x_{p_k} using polynomial time algorithms based on robust semidefinite programming, as shown in [23].

Assumption 1: For any v_o, $v_f \in \mathcal{X}$, there exists a finite sequence $\{x_p(0), \ldots, x_p(t): v_o = x_p(0), v_f = x_p(t), t \in \mathcal{T}\}$, such that $x_p(\tau) \in \mathcal{U}_p(x_p(\tau - 1))$ for each $\tau \in \mathcal{T}$.

Finally, we assume that in a single time step, the conditional probability of the evader being at a cell $x \in \mathcal{X}$ does not decay by more than a certain amount, unless one pursuer reaches x, in which case, the probability of the evader being at x may decay to zero if the evader is not there, or if it is possible to conclude from the measured data that an obstacle is at x with probability one. Such an assumption holds for most sensor models.

Assumption 2: There is a positive constant $\gamma \leq 1$, such that for any sequence $Y_t \in \mathcal{Y}_t^{\neg\text{fnd}}$ of $t \in \mathcal{T}$ measurements for which the evader was not captured

$$p_e(x, t+1|Y_t) \geq \gamma p_e(x, t|Y_{t-1}) \tag{8}$$

for any $x \in \mathcal{X}$ for which x is not in the list of pursuers' positions specified by the last measurement in Y_t, and the probability of an obstacle being at any given location given the measurements up to time t is strictly less than one for any pursuit policy $\overline{g}$.

3) Greedy Policies: Given the assumptions in the previous section, we now focus on finding efficiently computable suboptimal pursuit policies. We consider the following *greedy* policies: *local-max* and *global-max*. Both policies try to maximize the probability of capturing an evader at the next time instant, the difference being that local-max searches only one-step reachable cells, while global-max searches the entire map.

Local-Max Policy. Under this policy, pursuer k moves to the cell in the one-step reachable set with the highest probability of containing an evader over all the evader maps, that is

$$\mathbf{u}_k(t+1) = \underset{x \in \mathcal{U}(x_{p_k}(t))}{\arg\max} \ \underset{i=\{1\cdots n_e\}}{\max} p_{e_i}(x, t+1|Y_t)$$

where $p_{e_i}(x, t+1|Y_t)$ represents the probability of evader i being in cell x at time $t+1$ given the measurements Y_t.

Notice that the local-max policy is advantageous in scalability, since it assigns more importance to local measurements by searching only in $\mathcal{U}(x_{p_k})$, regardless of the size of the environment $\mathcal{X}$. This policy is computationally efficient, and can be computed independently by each pursuer in a decentralized pursuit–evasion game. However, it can be shown that in general, the local-max policy is not persistent on the average.

Global-Max Policy. The *global-max* policy searches over the entire map in order to compute the control that maximizes the probability of capturing an evader. Therefore, it is more computationally intensive and does not scale as well as the local-max policy with the size of $\mathcal{X}$. However, as we will show below, it has the nice property that it is persistent on the average.

Take an arbitrary sequence of measurements $Y \in \mathcal{Y}^*$, and compute the cell in the map with the maximum probability of having an evader

$$x^* \triangleq \underset{x \in \mathcal{X}}{\arg\max} \ \underset{i \in \{1, \ldots, n_e\}}{\max} p_{e_i}(x, t+1, |Y_t). \tag{9}$$

Next define the desired positions of the pursuers as

$$x_p^* \triangleq \underset{x_{p_1}, \ldots, x_{p_{n_k}} \in \mathcal{U}}{\arg\max} \ \underset{i \in \{1, \ldots, n_e\}}{\max} \sum_{k=1}^{n_p} p_{e_i}(x_{p_k}, t|Y_t). \tag{10}$$

Now define the global-max pursuit policy $g(Y)$ as

$$g(Y) \triangleq \text{nav}(x_p^*, k^*, Y) \tag{11}$$

where $k^* \in \{1, \ldots, n_p\}$ is the integer for which $x^* = x_{p_{k^*}}^*$. Here, nav: $\mathcal{U} \times \{1, \ldots, n_p\} \times \mathcal{Y}^* \to \mathcal{U}$ is an underlying "navigation policy" which takes a list of desired positions for the pursuers x_p^*, together with measurements Y_t, and produces a position reachable in a single time step that is "one step closer" to x_p^*, or concludes that there is an obstacle at x_p^*.

Theorem 1: If *Assumptions 1* and *2* hold, then the global-max policy $g: \mathcal{Y}^* \to \mathcal{U}$ is an admissible pursuit policy which is persistent on the average with period $T \triangleq d$, where d is the maximum number of steps needed to travel from one cell to any other. Moreover, $P(\mathbf{T}^* < \infty|\mathbf{g} = g) = 1$, and $E_g[\mathbf{T}^*] \leq n_e T \epsilon^{-1}$, with ϵ as in (7) and $\delta = \gamma^d/n_c$ in *Lemma 2*.

Proof: By definition of the navigation policy, g is admissible. In order to prove that g is persistent on the average, we show that the hypotheses of *Lemma 2* hold. From the definition of x^* in (9), we have that for any $t \in \mathcal{T}$

$$\underset{i \in \{1, \ldots, n_e\}}{\max} p_{e_i}(x^*, t|Y_t) \geq \frac{1}{n_c}$$

where n_c is the number of cells in $\mathcal{X}$. Now, since a pursuer takes, at most, d steps to reach x^*, by following policy g there must exist some $\tau \in \{t, \ldots, t+T-2\}$ with $T = d$, such that there is a pursuer just one step away from x^*. Consider such a time τ and set $x_p = g(Y_\tau)$. Therefore, the conditional probability of finding an evader at time $\tau + 1$ is given by $h_g(Y_\tau) \triangleq$

$$h_g(Y_\tau) = \underset{i \in \{1, \ldots, n_e\}}{\max} \sum_{k=1}^{n_p} p_{e_i}(x_{p_k}^*, \tau|Y_\tau).$$

By *Assumption 2* and the fact that it takes, at most, d steps to reach x^*, we have

$$\geq \underset{i \in \{1, \ldots, n_e\}}{\max} p_{e_i}(x^*, \tau|Y_\tau) \geq \delta \triangleq \frac{\gamma^d}{n_c} > 0.$$

Applying *Lemmas 1* and *2* shows that if the first evader to be captured is evader i, then $\text{Prob}(\mathbf{T_i^*} < \infty \ |\gg= \mathbf{g}) = \mathbf{1}$ and $E_g[\mathbf{T_i^*}] \leq \mathbf{T}\epsilon^{-1}$. Therefore, $\text{Prob}(\mathbf{T^*} < \infty \ |\gg= \mathbf{g}) = \mathbf{1}$ and $E_g[\mathbf{T^*}] \leq \mathbf{n_e T}\epsilon^{-1}$ ∎

D. Intelligent Evasion

Even though the pursuit policies described in the previous section are designed for a randomly moving evader only, in Section IV we will apply these policies to the case of an intelligent evader. We allow an intelligent evader to build a map of obstacles and pursuers and to employ either a local-min or global-min policy so as to minimize the probability of being captured. The local-min and global-min evasion policies are defined similarly to the local-max and global-max pursuit policies.

E. Vision-Based Detection of Obstacles and Evaders

Assume that the pursuers are equipped with a camera to sense the environment. We show how to estimate the position of obstacles and evaders from their observed positions in the image plane, the pose (rotation and translation) of the camera, and that of the pursuer. We define the coordinate frames: a) inertial frame, b) UAV frame, c) camera base, d) camera head, and e) UGV frame, and let $g_{ij} \triangleq (R_{ij}, p_{ij}) \in SE(3)$ be the relative pose of frame i with respect to frame j. Also, let $\hat{w} \in so(3)$ be the skew-symmetric matrix associated with axis $w \in \mathbb{R}^3$, and (e_1, e_2, e_3) be the usual basis for $\mathbb{R}^3$. If the observer is a

UAV, then $g_{ab} = (\exp(\widehat{e_3}\psi)\exp(\widehat{e_2}\theta)\exp(\widehat{e_1}\phi), p_{ab})$, where (ψ, θ, ϕ) are the estimates of the yaw, pitch, and roll angles of the helicopter, and $p_{ab} \in \mathbb{R}^3$ is the estimate of its position. $g_{bc} = (R_{bc}, p_{bc})$ is a predefined (known) transformation and $g_{cd} = (\exp(\widehat{e_2}\alpha)\exp(\widehat{e_1}\beta), 0)$, where (α, β) are the estimates of the pan and tilt angles of the camera. Then, the pose of the camera head with respect to the fixed inertial frame is given by

$$(R_{ad}, p_{ad}) = (R_{ab}R_{bc}R_{cd}, R_{ab}p_{bc} + p_{ab}). \qquad (12)$$

Let $\mathbf{x}$ be the estimate of the position of an obstacle (evader) in the image plane. Then its 3–D position is obtained as

$$q = \frac{(z_0 - e_3^T p_{ad})}{e_3^T R_{ad}A^{-1}\mathbf{x}} R_{ad}A^{-1}\mathbf{x} + p_{ad} \qquad (13)$$

where z_0 is the (fixed) z coordinate of the evader on the ground, assuming a flat terrain, and $A \in \mathbb{R}^{3\times3}$ is the camera calibration matrix.

If obstacles (evaders) are being observed by a ground pursuer, equation (13) can still be applied with minor changes. Replace frame b) by frame e), the UGV frame. Then $R_{ae} = \exp(\widehat{e_3}\gamma)$, where γ is the estimate of the heading of the UGV, p_{ae} is the estimate of the position of the observer, and g_{ec} is also a predefined (fixed) transformation.

The vision system is also used to estimate the visibility region of each vehicle. For a ground pursuer or evader, the visibility region is defined as the trapezoid whose vertices are computed from (13), applied to the vertices of a fixed rectangle located below the horizon on the image plane. For an aerial pursuer, since the camera is pointing down, the rectangle on the image plane is chosen as the whole image, which results in an approximately rectangular visibility region.

III. System Architecture

In order to implement the pursuit–evasion game scenario on real UAVs and UGVs, we propose a hierarchical hybrid system architecture that segments the control of each agent into different layers of abstraction, as shown in Fig. 2. The different layers allow for the same high-level intelligent control strategies to be applicable to both UAVs and UGVs. By abstracting away the details of sensing and control of each agent, we gain the interoperability of a unified framework for high-level intelligent pursuit policies across all platforms.

This section gives an overview of the different layers of abstraction of our system architecture, and some details about the implementation on our fleet of UAVs and UGVs. Our architecture design was inspired by the architectures of automated highway systems [24], air traffic management systems [25], and flight management systems [26].

A. High Level: Strategy Planner and Map Builder

The *Strategy Planner* is responsible for the high-level intelligent control of the vehicles, i.e., the pursuit policy computation described in Section II-C. It maintains a state-space of the system useful for mission planning, and tasks the agents according to mission objectives.

The *Map Builder* gathers sensor information from each vehicle and computes probabilistic maps with the locations of obstacles and evaders as described in Section II-B.

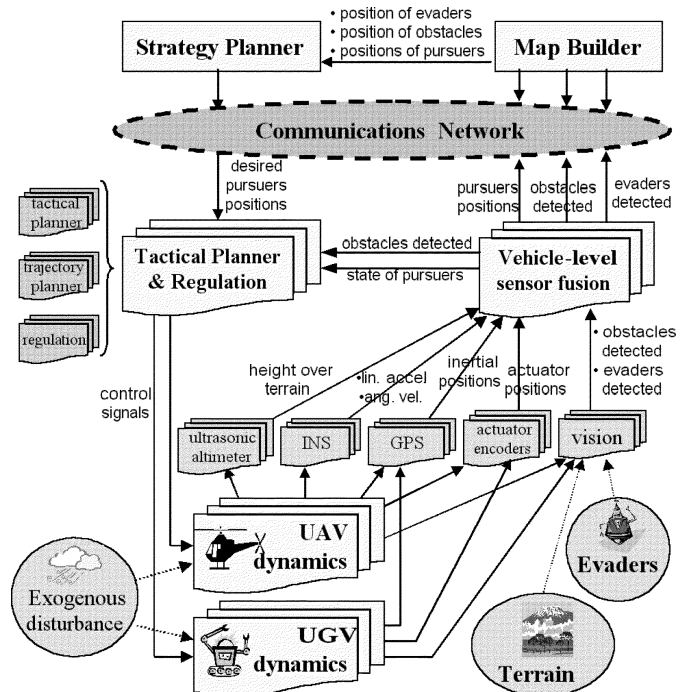

Fig. 2. System Architecture: Strategy planning and map building are implemented in MATLAB and run in a laptop which is also used for visualization. Tactical planning, regulation, and sensing are implemented in C++ and run in the UAV or UGV computers.

B. Low Level: Tactical Planner, Regulation, and Sensing

The *Tactical Planner* uses the state information maintained by the strategy planner for controlling the motion of each vehicle. It converts strategic plans into a sequence of way points or flight modes, which are used by the *Trajectory Planner* to produce a realizable and safe trajectory based on a dynamic model of the vehicle and safety routines such as obstacle avoidance. The final trajectory is sent to the *Regulation Layer*, which performs the real-time control of the vehicle along the specified trajectory.

Each vehicle makes observations about the environment using a vision system and about its state using a variety of sensors for position and orientation. Sensor-fusion techniques are used to improve the quality of the measurements.

C. Implementation of High Level Control Layers

We implemented the *strategy planner* and *map builder* in a MATLAB/Simulink environment as a part of a unified platform on which to conduct both simulations and experiments. Furthermore, we used a transmission control protocol (TCP) interface to connect the MATLAB-based strategy planner and map builder with the UAVs and UGVs through the wireless LAN.

With this unified platform, we are able to seamlessly combine experiments and simulations. In simulation mode, the strategy planner sends control commands over TCP to a UAV simulator obtained from system identification [9] and to a UGV simulator. Visibility regions are simulated according to the state variables of each vehicle, and the detection of evaders and obstacles is simulated with probabilistic sensor models. In experiment mode, the *same* strategy planner sends commands over TCP to the actual UAVs and UGVs, while the *same*

map builder receives vehicle locations from the GPS/Inertial Navigation System (INS), and visibility regions and locations of obstacles and evaders from the vision system.

D. Implementation of Low Level Control Layers

Our UAVs fleet consists of custom-designed UAVs based on Yamaha R-50 and R-Max industrial helicopters. The trajectory planner and regulation layers are implemented in C on an embedded PC running the QNX real-time operating system (OS). The low-level controller has a TCP interface that asynchronously receives desired setpoints from the high-level strategy planner, and reports the UAVs' current position. The vision system used to detect obstacles and evaders is implemented in C++ on a second PC running Linux. See [9] and [27] for further details.

Our UGVs fleet consists of ActivMedia Pioneer 2-AT all-terrain ground robots. The tactical/trajectory planner and regulation layer run on a microcontroller, while the vision system runs on a PC running Linux. See [8] for details.

UAVs and UGVs share the following components for sensing and communication: IEEE 802.11b wireless LAN connectivity, differential GPS, a PC104 Pentium 233MHz-based PC running Linux, and a color-tracking vision system. All these components are described in detail in [8].

IV. SIMULATION AND EXPERIMENTAL RESULTS

In this section, we present simulation and experimental results of pursuit–evasion games on our fleet of UAVs and UGVs.[3] Table I presents the mean capture time of 10 simulations between three pursuers and one evader with random initial conditions. Simulations 1–4 evaluate the performance of the two pursuit policies against a randomly moving evader for two types of visibility regions: an omnidirectional view S_{p_k}[4] and a trapezoidal view T_{p_k}.[5] Simulations 5–8 evaluate the performance of the global-max policy with a trapezoidal view for different speeds and levels of intelligence of the evader.

Table II presents results of real experiments between three UGV pursuers and one UGV evader. Fig. 3 shows the evolution of Experiment 1 through photographs and corresponding snapshots created by the map builder. The darker cells in the map

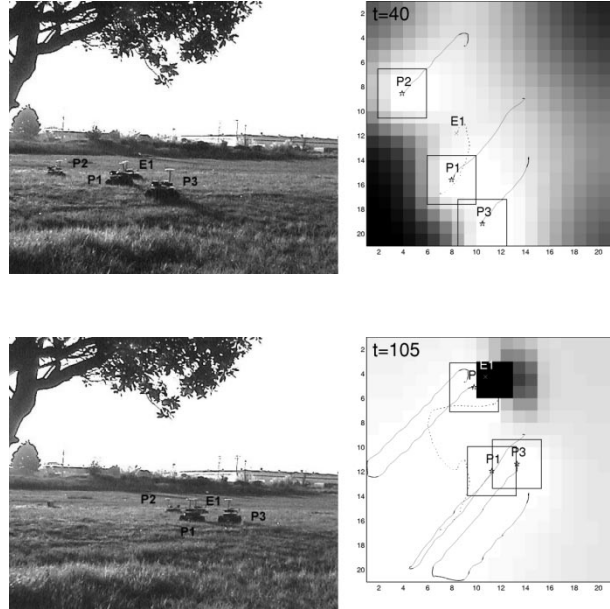

Fig. 3. Experiment 1: An actual game between three UGV pursuers and one UGV evader. The pursuers P1, P2, and P3 ($\star$) move at 0.3 m/s and use the global-max policy with an omnidirectional visibility region. The evader E1 moves randomly at 0.1 m/s.

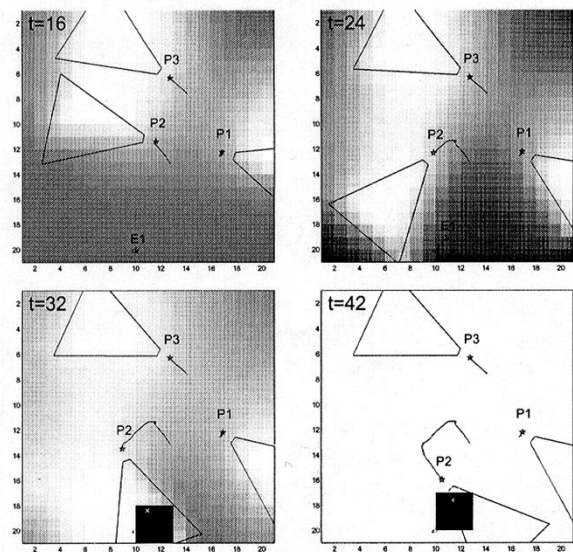

Fig. 4. Experiment 2: Three UGV pursuers versus a *slow* UGV evader.

represent regions with higher probability of having an evader. Figs. 4 and 5 show the map-building snapshots for Experiments 2 and 3, respectively.

Fig. 6 shows snapshots from Experiment 4: A game with one UAV and two UGV pursuers and one evader. The game parameters were similar to those in Table II: Pursuer speed was 0.3 m/s,

---

[3] All the experiments are performed in a 20 m × 20 m environment with 1 m × 1 m square cells, $p = q = 0.1$, and $d_m = 1.5$ m.

[4] $S_{p_k}(t)$ is a square of side 5 m, centered at $x_{p_k}(t)$.

[5] We are using the set difference operator /-> $T_{p_k}(t) \triangleq \triangle(x_{p_k}(t), 45°, 7$ m$)/\triangle(x_{p_k}(t), 45°, 1$ m$)$, where $\triangle(x, \theta, h)$ denotes an isosceles triangle with vertex x, height h, and angle θ.
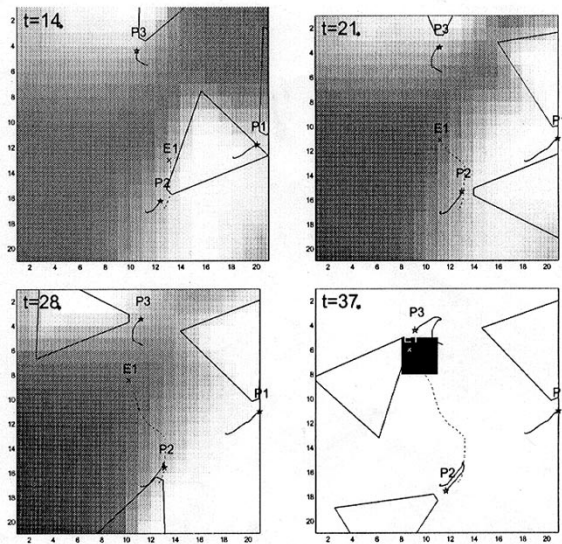

Fig. 5.   Experiment 3: Three UGV pursuers versus a *fast* UGV evader.

Fig. 6.   Experiment 4: one UAV and two UGV pursuers versus one UGV evader. (a) Initial configuration, evader on the left. (b) UAV pursuer detects evader. (c) UGV pursuers head toward global-max. (d) UGV pursuer captures evader.

evader speed was 0.1 m/s, the evader moved randomly, pursuers had trapezoidal visibility regions, and followed the global-max policy. The capture time was 30 s.

A. Discussion of Simulation and Experimental Results

Capture Time versus Visibility Region: Simulations 1–4 in Table I and Experiments 1–3 in Table II show that, regardless of the pursuit policy, pursuers with trapezoidal vision outperform those with omnidirectional vision. Even though at a given time instant both visibility regions cover approximately the same number of cells, a pursuer with a trapezoidal view can change its heading, thus covering many more *new* cells than a pursuer with an omnidirectional view. This agrees with natural predator/prey systems.

Capture Time versus Pursuit Policy: Simulations 1–4 in Table I show that the global-max policy generally outperforms the local-max policy. This is expected since the global-max policy is persistent on average, while the local-max is not.

Capture Time versus Evasion Policy: Simulations 5–8 in Table I evaluate the global-max pursuit policy against an evader following either a random or a global-min evasion policy. Since the global-max pursuit policy is designed for a randomly moving evader, there is no guarantee that the expected capture time will be finite for the case of an intelligent evader. We conclude from the simulations that it takes longer to capture an intelligent evader than a randomly moving one. Also, for a fast evader, it takes 300% longer to capture an intelligent one than a randomly moving one, while for a slow evader, it takes only 64% longer.

Capture Time versus Evader Speed: Simulations 5 and 6 in Table I show that it takes longer to capture a slower random evader than a faster random evader. This is because a faster random evader visits more cells in the map, increasing the chances of being detected. This argument can be applied to Fig. 5. The higher speed of E1 allows it to move away from the visibility region of P2 for $t \in [0, 14]$, but E1 soon moves into the visibility region of P3 and is quickly captured.

UAV Pursuer versus UGV Pursuer: Simulation results in [28] and Experiment 4 show that the local-max policy has a similar performance with either a UAV or UGV pursuer, while the global-max policy performs better with a UAV pursuer.

V. CONCLUSIONS

We presented a probabilistic approach to pursuit–evasion games involving UAVs and UGVs. We considered two computationally feasible greedy pursuit policies: *local-max* and *global-max*. We proved that for the global-max policy there exists an upper bound on the expected capture time which depends on the size of the arena, and the speed and sensing capabilities of the pursuers. Next, we presented an implemention of the scenario on a fleet of UAVs and UGVs based on a hierarchical hybrid system architecture. Finally, we presented several experiments, evaluating the performance of the proposed pursuit policies with respect to the speed and intelligence of the evaders and the sensing capabilities of the pursuers. Our results show that the global-max pursuit policy outperforms the local-max policy in a realistic situation in which the dynamics of each agent are included and computer vision is used to detect the evaders.

René Vidal received the B.S. degree from the Universidad Católica de Chile in 1997, and the M.S. degree in 2000 from the University of California at Berkeley, where he is currently working toward the Ph.D. degree in electrical engineering and computer sciences.

His research interests include multiple view geometry, motion segmentation, omnidirectional vision, vision-based control of mobile robots, hybrid systems, and game theory.

Omid Shakernia received the B.S. and M.S. degrees in electrical engineering and computer sciences in 1997 and 1999, respectively, from the University of California at Berkeley, where he is currently working toward the Ph.D. degree in electrical engineering and computer sciences.

His research interests include computer vision, vision-based control of mobile robots, omnidirectional vision, hybrid systems, and game theory.

H. Jin Kim (S'98–A'01) received the B.A. Ss. degree from the Korea Advanced Institute of Science and Technology, Daejon, Korea, and the M.S. and Ph.D. degrees in mechanical engineering from the University of California at Berkeley (UCB) in 1999 and 2001, respectively.

She is currently a Postdoctoral Researcher at the Electrical Research Laboratory at UCB. Her current research interests include machine learning in control systems, robust control, and modeling of unmanned vehicles.

Dr. Kim is a member of AIAA.

David Hyunchul Shim (M'02) received the B.S. and M.S. degrees from Seoul National University, Seoul, Korea, in 1991 and 1993, respectively, and the Ph.D. degree from the University of California at Berkeley in 2000, all in mechanical engineering.

He is currently a Staff Engineer in the Advanced Technology Group, Maxtor Corporation, Milpitas, CA. His research interests include unmanned aerial vehicles, hierarchical motion control systems, and high-performance positioning systems.

Dr. Shim is a member of ASME and AIAA.

Shankar Sastry (F'95) received the Ph.D. degree in 1981 from the University of California at Berkeley.

He was on the faculty of Massachusetts Institute of Technology, Cambridge, MA, as Assistant Professor from 1980 to 1982, and Harvard University, Cambridge, MA, as a chaired Gordon McKay Professor in 1994. He is currently Professor and Chairman of the Department of Electrical Engineering and Computer Sciences, University of California at Berkeley. He has coauthored over 250 technical papers and eight books, including *Nonlinear Systems: Analysis, Stability and Control* (New York: Springer-Verlag, 1999). His areas of research are embedded and autonomous software, computer vision, nonlinear and adaptive control, robotic telesurgery, control of hybrid systems, embedded systems, sensor networks and biological motor control.

Dr. Sastry was elected into the National Academy of Engineering in 2001.
